## I. Introduction

This paper examines evidence from a multi-country survey of subjective well-being (SWB) to investigate two questions. The first is whether the survey shows evidence of the existence of a phenomenon that can be interpreted as a midlife crisis. The second is whether there is any evidence of an association between a country's average SWB and each of two macro indicators, GDP per capita and government consumption expenditure. The policy relevance and intellectual significance of these questions has been verified by introspection. Trust us.<sup>[1]</sup>

The regression analysis of the survey data reported in this paper suggests that, across the lifespan, SWB follows the classic inverted U pattern, but turned upside down.<sup>[2]</sup> The nature of the association we observe between country averages of SWB and GDP per capita depends heavily on one influential case, namely the US. When the US is included in the sample, one can argue for a positive association; if the US is excluded, there is weak evidence of a negative association. The association between SWB and government consumption appears to be negative, although the US is again an outlier. The evidence for the negative association becomes clearer when the US is excluded.

## II. Previous literature

This paper contributes to large and still growing literature that uses surveys of SWB to investigate a variety of socio-economic questions. The seminal work in this literature is Easterlin (1974), which focused on the association between SWB and various notions of income and socio-economic status. By one interpretation, Easterlin's results suggest that we should expect to find little association between average income and average happiness in cross-sectional, country-level data. The pattern of SWB over the life cycle has been studied by Blanchflower and Oswald (2007), who find evidence of a U-shaped trajectory. They apparently fail to recognize, however, the deep resonance-of an anti-isomorphic nature-of the trajectory they observe with the classic inverse U pattern.

## III. Data

The survey data used in this paper are taken from Pew Research Center Global Attitudes Project (2002a). This survey consisted of interviews of between about 500 and 2,500 individuals conducted in each of 44 countries in 2002. In 37 of the countries included in the Pew survey, the number of respondents was less than 900. We chose to drop all observations from those 37 countries, which left us with a sample of individuals from 7 countries: China, India, Indonesia, Jordan, Pakistan, the Russian 1 This paragraph is a rip-off from Matthew

Rabin, who made a similar quip during a seminar he gave at UC Berkeley around 1990 or 1991 (about a new concept he was developing called fairness equilibrium). 2 Commentators not well-versed in economics sometimes reveal their lack of sophistication by calling this pattern a U. 3 Federation and the United States. Of the many variables based on respondents’ answers to social, political and economic questions, two were extracted for this paper. We gave these variables the names SATIS and AGE. The variable SATIS is our measure of SWB. Values of this variable were elicited as follows: Respondents were presented with a vertically ordered scale of integers, ranging from 10 at the top of the scale to 0 at the bottom, and the interviewer then asked: Here is a ladder representing the “ladder of life.” Let’s suppose the top [a value of 10] of the ladder represents the best possible life for you; and the bottom [a value of 0], the worst possible life for you. On which step of the ladder do you feel you personally stand at the present time? (Pew Research Center Global Attitudes Project, 2002b, p. 6) The variable AGE represents the respondent’s age in years at the time of her or his last birthday. We also generated the variable AGE-SQUARED to use in the exploration of a possible non-linear association between age and SWB. Two macro indicators were taken from World Bank (2014). GDP\_PC shows the income per capita of each country for 2002, expressed in current US dollars. GOV\_CON shows government consumption expenditure as a share of GDP, again for 2002. The variable CM\_SATIS, representing country means of SATIS, was constructed for use as a measure of SWB in country-level analyses

## IV. Descriptive statistics

Table 1 shows the values of CM\_SATIS, GDP\_PC and GOV\_CONS for each of the seven countries in the sample.

Table 1: Table 1: Mean Satisfaction, GPD per capita and Government Consumption by Country

country.name	cm_satis	inc	exp
China	5.174480	1135.4479	15.590028
India	5.085851	486.6405	11.890161
Indonesia	5.761539	909.8873	7.257458
Jordan	5.343716	1901.5804	22.695573
Pakistan	5.472683	483.0319	8.723921
Russian Federation	4.741266	2375.1579	17.953634
United States	7.019277	38175.3764	15.039799

## V. Analysis and results

To investigate whether the data contain evidence of the phenomenon of a midlife crisis, we did an OLS regression of *SATIS* against *AGE* and *AGE\_SQUARED*. The results of this regression are shown in Column 1 of Table 2.

We ran another OLS regression of *SATIS* against *AGE* and *AGE\_SQUARED*, this time including country fixed effects. The results of this regression are shown in Column 2 of Table 2.

In both regressions, the coefficient on *AGE* is negative and the coefficient on *AGE\_SQUARED* is positive, and in all four cases the p-values are below 0.0005. In both regressions, therefore, the fitted value of *SATIS* follows an upside-down inverted-U pattern with respect to *AGE*, and reaches a unique interior minimum. We will call the age at which the minimum fitted value of *SATIS* occurs the “age of minimum SWB.”

If we use  $\hat{\beta}_{AGE}$  to represent the estimated coefficient on *AGE* and  $\hat{\beta}_{AGE-SQUARED}$  to represent the estimated coefficient on *AGE-SQUARED*, then the age of minimum SWB is equal to  $-\frac{\hat{\beta}_{AGE}}{2\hat{\beta}_{AGE-SQUARED}}$ . Using the estimated coefficients from our regressions we find:

Column 1 (no country fixed effects): Age at minimum SWB=47.76  
Column 2 (with country fixed effects): Age at minimum SWB=53.90

Depending on which specification we use, we find that the age at minimum *SWB* is about 47 years and 9 months or 53 years and 11 months. We interpret this pattern, in which estimated age at minimum SWB is within a few years of 50, as evidence in favor of a phenomenon that can be called a midlife crisis.

To examine the association between country means of SWB and GDP per capita, we construct the scatterplot shown in Figure 1. The OLS line through those points would probably be upward sloping, and maybe even statistically significant. However, such a result would be influenced heavily by the observation for the US. It appears that if the US were dropped from the sample, the association might in fact be negative.

To examine the association between country means of SWB and GDP per capita, we construct the scatterplot shown in Figure 2. The OLS line through those points would probably be downward sloping, and maybe even statistically significant. Again, however, the US is an outlier. In this case, it appears that dropping the US would lead to a much cleaner negative association.

## VI. Conclusion

The analysis presented in this paper provides evidence of an upside-down inverted U relationship between SWB and age, with minimum SWB occurring within a few years of 50. This result is consistent with the findings of Blanchflower and Oswald (2007). The country-level, cross-sectional associations between mean SWB and GDP per capita and between mean SWB and government consumption expenditures depend heavily on whether the US is included in the sample. 3 A careful analysis would include also things like robustness tests and other forms of sensitivity analysis, as well as consideration of the magnitude or practical significance of the estimated coefficients. To maintain the realism of this paper as an example of economic research, such considerations are omitted. 5
